*Fusobacterium nucleatum* is a morbidic agent in periodontitis and halitosis. Egg yolk antibody (IgY) was obtained from egg yolks from chickens stimulated with *F. nucleatum*. This study was to assess the effectiveness of IgY on periodontitis and halitosis caused by *F. nucleatum* in vitro and in vivo. The growth of *F. nucleatum* was inhibited (*p < 0.05*) by different concentrations of IgY in vitro and the results of a Halimeter show volatile sulfur compounds (VSCs) were reduced to 904 ± 57 ppb at a concentration 40 mg/ml of IgY. The changes of fatty acids of *F. nucleatum* were determined using GC-MS. The scores for odor index of rat saliva were decreased. The major constituent of volatile organic compounds (VOCs) including short-chain acids decreased 46.2% in 10 mg/ml IgY, ammonia decreased 70% in 40 mg/ml IgY, while aldehydes and olefine ketones were almost unchanged. The ELISA assay revealed that IL-6 and TNF-α were decreased after 4 weeks’ IgY treatment. Morphometric (X-ray) and histological analyses (HE) showed that IgY reduced alveolar bone loss and collagen fibers became orderly in rat models. As a result, IgY may have the potential to treat periodontitis and halitosis.

**Keywords:** Egg yolk antibody, *Fusobacterium nucleatum*, halitosis, inflammation, alveolar bone loss

Introduction

Halitosis, a nasty odor emanating from the mouth, is a multi factorial disease. Bad breath is primarily related to volatile sulfur compounds (VSCs) including hydrogen sulfide (H₂S) and methyl mercaptan that are produced by bacteria [1]. Moreover, butyric acid, methyamine, indole, dimethylamine, cadaverine, acetone and propionic acid are some other volatile organic compounds (VOCs) that may also contribute to oral malodor [2, 3]. The main causes of bad breath are associated with tongue coating, and gingival as well as periodontal disease. Periodontitis is a chronic inflammatory disease of multifactorial etiology which is mainly caused by pathogenic bacteria. Periodontal disease can lead to pain and discomfort, impaired tissues of the teeth, and tooth loss [4]. The infection can spread and affect the entire periodontium, even causing cardiovascular disease [5]. While oral malodor is not directly caused by periodontal disease, abundant evidence indicates that periodontal disease intensifies the severity of malodor. According to the reports, approximately 60% of patients with periodontitis produce volatile sulfur compounds (VSCs) [6, 7].

Among oral bacteria, *F. nucleatum* is a Gram-negative anaerobe that has pathogenic potential and is involved in halitosis as well as periodontal diseases [8]. *F. nucleatum* is...
in a minority in the oral cavity, but is widely detected elsewhere in the body in case of infectious conditions [9]. F. nucleatum has strong invasive activity toward human gingival epithelial cells, and directly contributes to periodontal disease by forming a bridge with other virulent anaerobes [10]. Furthermore, F. nucleatum also produces large amounts of volatile sulfur compounds (VSCs) and is a representative bacterium in halitosis [1]. Available treatments, such as chemical antiseptics, antibiotics and mechanical therapy, are effectively used for halitosis and periodontitis. However, antibacterial-resistant bacteria and the by-effects of antibiotics limit antibacterial therapy periodontitis. Therefore, this study investigated whether IgY extracted from the egg yolks of chickens treated with F. nucleatum was verified to be powerful as a medication for periodontitis. The growth inhibition assay was performed according to the previous method [19]. After amplifying in BHI media, the F. nucleatum was harvested by centrifugation and adjusted to a final concentration at an OD of 650nm of 0.5 (10^9 CFU/ml) in the AS. IgY against F. nucleatum (extracted from egg yolks after chickens were challenged with F. nucleatum) obtained from Maxam Ltd. (China). IgY was reconstituted to 40 (high-dose), 20 (mid-dose), 10 (low group) mg/ml in 3.9 ml liquid medium. Prepared AS that is free of IgY was used as negative and blank control. 200 ul F. nucleatum liquid containing 1.8 ml of AS and bacterial solutions were incubated at 37°C in an anaerobic environment. Aliquots of bacteria (2 ml) were taken at 0, 2, 4, and 6 h in sterile tubes, and absorbance was measured at 650 nm using a spectrophotometer (V5100B, METASH Ltd., China).

**Materials and Methods**

**Bacterial Strain and Culture Conditions**

F. nucleatum (ATCC 25586) used in the present study was brought from American Type Culture Collection (Manassas, USA).

and the GC column temperature rose to 285°C at a rate of 8°C/min and then maintained at 285°C for 5 min. The AMSD 5973 mass-spectrometer was set on ion monitoring mode and focused at m/z 40–400 molecular ion. The temperature of the source was 230°C. Mass spectra were obtained at an energy level of 70 eV. The structure of the sample was identified by the National Institute of Standards and Technology (NIST) library. According to the software provided by the instrument, the interference peak is removed, then the chemicals are integrated. The proportion of the different components relative contention (Ab*s) is calculated.

Establishment of Periodontitis Rat Model

Specific-pathogen-free female Sprague Dawley (SD) rats (n = 10, weight 150 g ± 10 g) were purchased from SLA Laboratory Animal Co., Ltd (China). Rats were fed in individual cages and afforded sterile food and water under specific-pathogen-free condition. Rats are used for experiments when they are 9–10 weeks old and are handled according to guidelines set by the Ethics Committee of Shanghai Ocean University (China). For establishment of a halitosis with periodontitis rat model, maxillary bilateral second molar of the rats were ligatured with a sterile 5-0 silk (Sangon Biotech Co., Ltd., China). Then 100 μl live F. nucleatum (10^8 CFU/ml) mixed in PBS was smeared into each rat’s oral cavity three times a week and lasting four weeks to induce periodontal infection. After successful modeling, the diseased rats were divided into three groups (n = 3) randomly and given different treatments. In the experimental groups, 200 μl of different concentrations of IgY solutions were smeared one times into the oral cavity every day for 30 days. The same volume of 0.9% NaCl solution served as a negative control.

Organoleptic Measurements

Two experienced odor judges assessed malodor levels, as previously reported [21]. Judging scores were recorded on a range of 0 to 5, as follows: score 0, no distinct odor; score 1, almost no noticeable malodor; score 2, minor, but clearly notable malodor; score 3, mild malodor; score 4, strong malodor; score 5, extremely noticeable malodor. The saliva was obtained by sterile cotton swabs wiping for 30 sec in the oral cavity of the rats from each treatment. The swabs were placed immediately into a 10-ml headspace vial with a screw top lid (CNW, Anple, China). Judges immediately sniffed the malodor emanating from each test tube to assess malodor levels.

Measurement of Malodor Compounds from Rat Saliva

The new collection of saliva samples were placed into vials and placed in a water bath adjusted to 45°C. Three replicates per each sample were prepared and analyzed. After 30 min, headspace VOCs were volatilized and adsorbed on a SPME fiber (65 μm, PDMS/DVB; Anple, China). SPME fiber was desorbed at 250°C for 5 min in the injector port of a GC connected with a mass detector with a scan range from 40 to 400. The initial column temperature was set at 50°C, then ascended at 10°C/min to 150°C then 5°C/min to 250°C and maintained for 2 min. The conditions of MS followed the above.

IgY Effect on Levels of IL-6 and TNF-α

Heart blood was collected from the groups after 4 weeks’ different treatment. After centrifugation at 12,000 ×g for 8 min, the supernatants were transferred to a new tube. According to the manufacturer’s instructions, we used enzyme-linked immunosorbent assay kits (ELISA) (Mibio, China) to measure the concentration of TNF-α and IL-6. All samples were measured in triplicate repetition with provided standards. The ELISA wells were examined using a microplate reader (SH-100, USA) at a wavelength of 450 nm.

Histopathological Analysis

After collecting blood samples, the maxillary molar regions of the rats were dissected from each rat and fixed in 4% paraformaldehyde sodium phosphate buffer for 36 h. Radiographic images of the maxillary were taken by an X-ray machine (Faxitron MX-20 DC12 system; 119 Faxitron Biopics, Lincolnshire, USA). The bilateral mandibles were demineralized in formic acid (10%) at room temperature for one week. Then bilateral mandibles were embedded in paraffin; bilateral mandibles were cut into 4-μm thick sections using a microtome (Leica RM2235, Germany). Samples were stained with hematoxylin and eosin according to H&E protocol using light microscopy (Lecia, Germany) to observe histopathology.

Statistical Analysis

Statistical analysis was performed using SPSS 18.0 ((SPSS Inc., USA). All data were represented as means ± standard deviation (S.D.) and were analyzed using Student’s t-tests. P < 0.05 was considered statistically significant.

Results

Growth Inhibition of IgY to F. nucleatum In Vitro

To examine the capability of IgY to inhibit growth of F. nucleatum in artificial saliva, we cultured bacteria in the tubes adding different concentrations of IgY for 0, 2, 4, and 6 h. Growth curves of F. nucleatum in media with IgY concentrations of high-dose (40 mg/ml), mid-dose (20 mg/ml), low-dose (10 mg/ml) and blank are shown in Fig. 1. After adding IgY, the turbidity of media decreased. The phenomenon mainly stems from the fact that F. nucleatum increased after the treatment with IgY. In these cases, growth was significantly inhibited by the addition of high-dose specific IgY (p < 0.01) compared with the control group. 10 mg/ml (low-dose) and 40 mg/ml (mid-dose) groups had less of a decrease in bacterial counts than the high-dose one. The capability of 10 mg/ml (low-dose) group to inhibit growth is similar to 20 mg/ml (mid-dose) (p < 0.05) compared with the control group.
Halimeter is an effective instrument that measures total breath VSCs by electrochemical sensors. VSC production by *F. nucleatum* was measured in the process of different doses of IgY. As shown in Table 1, the concentration of IgY was related to the production of VSCs. More specific, high-dose IgY was associated with the production of 904 ± 57 ppb compared to 1,921 ± 99 ppb in the absence of IgY. In other words, there is a significant trend of decreasing after adding the high-dose IgY (*p* < 0.01). Supplementing the culture medium with mid-dose IgY and low-dose IgY only slightly decreased VSCs levels produced by *F. nucleatum*. The inhibition effect increased as the concentration of specific IgY increased in the range of medium to high concentrations. The effect of mid-dose IgY is almost the same as that of low concentration.

The Changes of Fatty Acids In Vitro by IgY

Fatty acids produced by microbial metabolism are significant characteristics in species and quantities. Most bacterial acids are bounded with arguer molecules, such as phospholipids, glycolipids. Free acids, which are extracted with solvents, are found by GC-MS. The long-chain fatty acids were detected by GC-MS. C16:0, C16:1, and C18:0, the main components from the metabolic production of *F. nucleatum* in the artificial saliva, accounted for about 80% in fatty acids. No marked differences were found between control group and IgY groups regarding C18:1. The results indicate that the relative content of C16:1 decreased 28.6% compared with the control in Fig. 2. Trace amounts of 14-methyl-C15:0 were detected in artificial saliva. The percentage of C18:0 and C16:0 significantly decreased (*p* < 0.05) after the treatment of high-dose IgY.

The Changes of Odor Index

When *F. nucleatum* was incubated orally in mice, the odor judges’ scores were high. Furthermore, the addition of high-dose IgY (40 mg/ml) to the rat orally significantly lowered both judges scores (Fig. 3) (*p* < 0.05), as compared with the blank control. In the presence of 10 mg/ml IgY, malodor production was higher than high-dose IgY, but judge scores were lower than blank control (*p* < 0.05).
The Changes of Volatile Organic Compounds (VOCs) In Vivo by IgY

The Halimeter does not record all the odor vectors present in the breathed air. Volatile organic compounds (VOCs) in saliva of animal models were detected using SPME-GC-MS. A total of 17 compounds were found to be ubiquitous in all samples in the present study, which included 4 alcohols, 4 carboxylic acids, 3 ketones, 2 aldehydes, 2 esters and 1 nitrogen compound (Table 2). According to the previous literature, all the compounds were divided into six categories. A1 represents alcohol, A2 represents aldehydes, A3 represents ketone, A4 represents carboxylic acid, A5 represents ester, C represents nitrogen compounds. These VOCs are dominant classes of organic volatiles represented in the microbial production and release of chemicals. The proportion of different components relative contention (Ab*s) changes as shown in Fig. 4. Short-chain acids account for the largest proportion, with butyric acid accounting for about 13% of short-chain acids. After treatment of IgY, butyric acid, hexanoic acid, propionic acid and acetic acid are significantly reduced (p < 0.05).

Another important substance, ammonia (C), is decreased by high-dose (40 mg/ml) and low-dose (10 mg/ml) IgY. The high decrements of abundances contain short-chain acids, ammonia and alcohol, which indicates that these ingredients are sensitive in volatile odors. High-dose IgY significantly decreased ingredients that have a pungent smell, low-dose IgY decreased the amount of reduction is less than high-dose IgY (Fig. 4). However, aldehydes (A2) and ketone (A3) were almost unchanged in the negative control.

IgY Effect on Levels of IL-6 and TNF-α

To evaluate the response of *F. nucleatum* stimulation on rats’ TNF-α and IL-6, rat oral cavity was incubated with *F. nucleatum*. After treatment with different concentrations of IgY, IL-6 and TNF-α were assessed by ELISA. The levels of the anti-inflammatory cytokine were higher in the control group compared to IgY-treated subjects after 4 weeks’ treatment. As shown in Fig. 5, the concentration of TNF-α and IL-6 after the treatment of 10 mg/ml (low-dose) were significantly decreased (p < 0.05) compared with

control group. IL-6 reduced from 11.2 ng/ml to 5.3 ng/ml at high dose IgY and TNF-α reduced from 7.3 ng/ml to 4.7 ng/ml. The concentration of IL-6 quite significantly ($p < 0.01$) decreased in high-dose group, and the level of TNF-α was significantly ($p < 0.01$) lower than control group, and the level of TNF-α was markedly ($p < 0.01$) lower than control group. Additionally, it was obvious that low-dose IgY groups reduced the IL-6 and TNF-α levels by about 7% and 9.6% compared to the level in the negative group.

### Alveolar Bone Loss and Histopathological Analysis

The mouse model of periodontitis caused by *F. nucleatum* infection was used to investigate the effect of IgY. The results of X-ray and histological examination by H&E staining were showed in Fig. 6. The results of X-ray showed that the gap between the teeth of the control group is large and the alveolar bone has a large gap between the teeth. After four weeks treatment of high-dose IgY, the gaps between teeth significantly reduce and alveolar bone is close to teeth. As shown in Fig. 6B, there is a clear trend of decreasing alveolar bone resorption after different concentration of IgY. Moreover, disorganization of the connective tissue and remarkable inflammatory infiltration and were observed in Fig. 6C. Effective rehabilitation of periodontium, including restoration of collagen fibers was detected in Fig. 6C. After 4-weeks’ treatment, high-dose (40 mg/ml) IgY significantly improved periodontal restoration.

### Discussion

Many in vitro studies have investigated that specific IgY has antimicrobial activity against a series of oral bacteria, such as *Salmonella enteritidis* [22], *F. nucleatum* [23]. Most research only investigated the inhibition of fungicide and metal ion in general medium. Saliva contains a complex mixing of protein, vitamin and ion, but the acquisition of saliva needs many volunteers and saliva has less reproducibility. In this in vitro study, the artificial saliva that has the similar components with natural saliva was used to simulate the human saliva that *F. nucleatum* grows in the oral cavity. With artificial saliva, it is easy to control macromolecular, ion and amino acids of the medium to manipulate their effect on *F. nucleatum* growth and metabolism [18]. In this study, specific IgY significantly reduced the amount of *F. nucleatum* (Fig. 1). The IgY targeted 40-kDa outer membrane protein of *P. gingivalis* has been proved that IgY can significantly inhibit the coaggregation of *P. gingivalis* with other bacteria [15]. Thus, IgY may effectively bind cell surface components including outer membrane proteins or lipopolysaccharides to inhibit *F. nucleatum* growth [17]. The cell membrane fatty acid of *Fusobacteria* strains contains C14:0, C16:0, and cis-9 C16:1 which are the primary fatty acids [24]. In this study, IgY reduces the amount of fatty C16:0, C16:1, and C18:0, which...
may indicate that IgY acts on the metabolism of fatty acids to inhibit F. nucleatum. At the same time, the changes of short-chain fatty acids in saliva may also be related to the reduction of long-chain fatty acids.

VSCs compounds including H2S and CH3SH dominate halitosis [25]. After the treatment of IgY, odor index significantly decreased, which indicates IgY prevents halitosis in vivo (Fig. 4). After the treatment of IgY, odor index significantly decreased, which indicates IgY prevents halitosis in vivo (Fig. 4). Bacterial enzymes, L-cysteine desulphhydrase and METase, produce VSCs by digesting amino acids [26]. However, many amino acid catabolic enzymes are situated in bacteria, which render antibodies unable to sufficiently affect them. Inhibition of microbial growth by antibodies is another effective alternative method. In our study, IgY was able to significantly reduce VSCs by inhibiting the growth of bacteria. Zinc ions have two mechanisms of malodor inhibition by binding with H2S and antimicrobial activity [27]. According to the reports, F. nucleatum produces VSC, which is related with Cdl (Fn1220) and Lcd (Fn0625) [28]. Cetylpyridinium chloride (CPC) has been found to impress the cdl expression in F. nucleatum. Meanwhile, CPC induces l-cysteine desulphhydrase expression [29]. IgY may influence the expression of VSC-related gene which was speculated.

This study used live F. nucleatum to imitate halitosis and periodontitis in mice oral cavity. In oral cavity, VSCs are one of the sources of bad breath; VOCs also are important parts of halitosis. VOCs in breath dissolve in saliva influencing its composition. Human saliva contains complex composition including peptides, proteins, and numerous volatile organic compounds. Various oral bacteria use different systems to degrade nutrients that produces various volatile organic compounds (VOCs). Several studies have investigated the volatile organic compounds in saliva. They reported that the presence of six types of compounds ketones, alcohols, aldehydes, esters and volatile acids [30]. The changes of salivary VOC composition may be an excellent indicator of halitosis through the treatment of IgY. Short-chains alcohols, ketones and esters are detected in our research. The methods of saliva collection also may influence its composition. So, a non-stimulated saliva collection approach was chosen in this study to avoid influence. Although rat oral cavity is different from human, the changes of VOCs are similar to human. After the treatment of IgY, odor index significantly decreased, which indicates IgY prevents halitosis. Volatile acids have a stimulating odor. IgY effectively inhibits halitosis by reducing part of the ingredients of VOCs. The model of rat may provide an effective method for development of anti-halitosis and anti-periodontitis drugs or antibodies in the future.

In this model, mechanical trauma caused by ligature destroys the integrity of tissue to induce an inflammatory response and periodontal ligament, which induces serious bone loss [32]. In vivo study, periodontitis rat without IgY treatment have significant bone loss compared with IgY treatment, accompanying collagen fiber disorder. Prior studies have noted that the anti-P. g IgY in the periodontitis disease could decrease the probing depth [33]. There are macrophages in dental pulp that are activated by TNF-α [34, 35]. Anaerobic bacteria produce many metabolic end products including short-chain fatty Acids. Secondly, volatile acids (e.g., butyric, acetic, isovaleric and propionic) are important parts of halitosis. Butyric and propionic acids have been proved that they have cytotoxicity to vero cells [36]. In this study, butyric acid, propionic acid and caproic acid are detected using SPE-GC-MS. Butyric acid is one of the major by-products of F. nucleatum. Butyric acid also can inhibit T-cell proliferation and stimulate the monocytes and neutrophils to produce proinflammatory cytokines [37] which increase the severity of periodontitis and halitosis. Our study is in agreement with previous studies that increased cytokine IL-6 and TNF-α in response to F. nucleatum [38]. Specific IgY targeting to F. nucleatum significantly inhibit cytokine, which may be related to the reduction of butyric acid.

In conclusion, IgY induces systemic immune responses to F. nucleatum and VSCs in a dose-dependent manner in vitro. SPE-GC-MS revealed that specific IgY possibly acts on mechanisms of F. nucleatum. The IgY has an effective impact on periodontal and halitosis disease caused by F. nucleatum in rat, which was further proved by its ability to decrease alveolar bone loss, inflammation and VOCs. F. nucleatum has also been involved in the pathogenesis of several diseases [39]. Most important, the study provides an effective strategy for the treatment of disease caused by F. nucleatum.
